Abstract

Current methods for estimating vegetation parameters are generally sub-optimal in the way they exploit information and do not generally track uncertainties. We look forward in the future to operational data assimilation schemes to track land surface processes and exploit multiple types of observation. Data assimilation schemes seek to combine observations and models in a statistically optimal way taking into account uncertainty in both, but have not yet been much exploited in this area. The EO-LDAS scheme and prototype, developed under ESA funding is designed to exploit the

27 anticipated wealth of data that will be available under GMES missions such as the Sentinel family
28 of satellites to provide improved mapping of land surface biophysical parameters. This paper
29 describes the EO-LDAS implementation, and explores some of its core functionality. EO-LDAS is a
30 weak constraint variational data assimilation system. The prototype provides a mechanism for
31 constraint based on a prior estimate of the state vector, a linear dynamic model, and Earth
32 Observation data (top of canopy reflectance here). The observation operator is a non-linear optical
33 radiative transfer model for a vegetation canopy with a soil lower boundary, operating over the
34 range 400 to 2500 nm. Adjoint codes for all model and operator components are provided in the
35 prototype by automatic differentiation of the computer codes.

36

37 In this paper, EO-LDAS is applied to the problem of estimating a subset of six of the parameters
38 controlling the radiative transfer operator over the course of a year (> 2000 state vector elements).
39 Zero and first order process model constraints are implemented and explored as the dynamic model.
40 The assimilation estimates all state vector elements simultaneously. This is performed in the context
41 of a typical Sentinel-2 MSI operating scenario, using synthetic MSI observations simulated with the
42 observation operator, with uncertainties typical of those achieved by optical sensors supposed for
43 the data.

44

45 The experiments consider a baseline state vector estimation case where dynamic constraints are
46 applied, and assess the impact of dynamic constraints on the *a posteriori* uncertainties. The results
47 demonstrate that reductions in uncertainty by a factor of up to two might be obtained by applying
48 the sorts of dynamic constraints used here. The hyperparameter (dynamic model uncertainty)
49 required to control the assimilation are estimated by a cross-validation exercise. The result of the
50 assimilation is seen to be robust to missing observations with quite large data gaps.

51

52 **1 Introduction**

53 **1.1 Background**

54 One of the primary goals of Earth Observation (EO) is to provide objective and reliable information
55 on the current and (particularly within the satellite EO era) historical state and dynamics of the
56 Earth environment. A major component of this that has been a significant focus of research efforts
57 on monitoring terrestrial vegetation, but EO data are usually of a radiometric nature and do not give
58 direct estimates of the properties of the Earth land surface that we wish to map. Some level of
59 *inference* is therefore needed.

60

61 Early studies in terrestrial vegetation monitoring from EO (Richardson and Wiegand, 1977; Tucker,
62 1979) found that simple transformations of multispectral measurements at red and near infrared
63 wavelengths gave a signal that was responsive to the relative amount of green biomass and that
64 could be used to track vegetation dynamics (Goward et al., 1985). The attractions of such
65 ‘Vegetation Indices’ (VIs) are obvious: they are visually impressive as spatial and temporal datasets;
66 they are simple to produce and provide a single quantity to interpret; they compensate for some of
67 the extraneous factors that can otherwise complicate lower level EO signals; and they can often
68 provide effective information for time series analyses, where the timing, rather than the magnitude
69 of events is of importance (e.g. vegetation phenology). Further, such indices can be directly targeted
70 at particular functional or physical vegetation properties, such as the fraction of absorbed
71 photosynthetically active radiation (fAPAR) or Leaf Area Index (LAI), by design (Gobron et al.,
72 2002, 2010) or empirically (Rochdi and Fernandes, 2010). In the former case a calibration is
73 achieved using a set of radiative transfer model runs over a range of conditions (Gobron et al.,
74 2000). In the latter, extensive ground-based measurements must be made (Chen et al., 2002) and the
75 form of the relationship with a particular VI assumed. Such efforts are fast to process and often
76 effective, especially for near-real-time survey. They have a range of known failings (Baret and
77 Guyot, 1991), but some of these, such as dependence on the angular conditions of data acquisition

78 can be reduced by treating the data to normalise for such effects (e.g. Rochdi and Fernandes, 2010).
79 Ultimately though, however much care is taken to treat such effects, methods assuming such fixed
80 mappings from VIs with ‘statistical’ models are open to many criticisms, some of the more
81 significant of which could be considered: (i) they fail to make full use of the information content of
82 the observational data; (ii) they (often) fail to make use of our understanding of the physics of the
83 situation; (iii) they need recalibration if conditions change (e.g. sensor band pass functions or scale
84 of observation); (iv) they tend not to treat uncertainty in the mapped product in any rigorous way
85 (mostly, they fail to consider this at all). This is a judgement call.

86

87 An alternative stratagem has been to build mathematical models of the physics of radiation
88 interactions with vegetation canopies and the intervening atmosphere, phrased as functions of
89 ‘control’ variables (polarisation, wavebands, viewing and illumination angles etc.) and (bio) physical
90 parameters or ‘state variables’ (LAI, leaf chlorophyll concentration etc. for the canopy, and aerosol
91 optical depth, ozone concentration etc. for the atmosphere), and to use these to attempt to interpret
92 the satellite signal. We may call these radiative transfer (RT) models. To tie in with discussions
93 below and to provide consistency with the data assimilation literature, such models are called here
94 ‘observation operators’ (denoted $H(x)$) in that they map from the state variable vector x to the EO
95 signal (as a vector) R for a given set of control variables, so the modelled signal vector $R = H(x)$.
96 The ‘remote sensing inverse problem’ then is to obtain an estimate of some function of x , $F(x)$
97 from measurements R . How this may be achieved is discussed in more detail below.

98

99 Much effort has been devoted to producing information from EO data about specific biophysical
100 quantities that are relevant to science and society. A major focus of this has been to attempt to
101 provide estimates of (green) LAI. Garrigues et al. (2008) consider four representative EO-derived
102 global LAI products, with core spatial resolutions of 1 km or coarser, that use what might be

103 considered state of the art methods for multi-year dataset generation. The reader is referred to that
104 paper for detailed information on the products, a product inter-comparison and validation against
105 independent ground measurements. The temporal resolution of the products varies from 8 days to 1
106 month. Three of the products (ECOCLIMAP, GLOBCARBON (V1), and CCRS) are derived from
107 assumed VI relationships with LAI. A fourth (MODIS (C4)) uses such a relationship for a backup
108 algorithm. Three of the products (GLOBCARBON, CYCLOPES (V3.1) and MODIS) make use of
109 RT models in attempting to estimate the LAI. In the case of GLOBCARBON the RT model is used
110 to calibrate the VI-LAI relationship. For MODIS a look up table derived from the RT model is used
111 to map red and near infrared (NIR) bidirectional reflectance data to LAI, and for CYCLOPES a
112 neural network derived from an RT model is used for the mapping from red, NIR and shortwave
113 infrared (SWIR) portions of the electromagnetic spectrum. A feature of these uses of RT models is
114 that they can map many channels of input data to one (or many) outputs. The one-to-one mapping
115 used in VI design and/or calibration is then just the simplest case of this more general RT approach.

116

117 A major new effort in satellite data provision is the GMES (Global Monitoring for Environment and
118 Security; www.gmes.info) programme (Council of the European Union, 2010). It is an EU initiative
119 set up to provide timely information on key environmental variables for policy makers and public
120 authorities, and is intended to be a major EU contribution to understanding and managing climate
121 change. Six thematic areas are being developed: marine, land, atmosphere, emergency and security
122 and climate change. The land monitoring service is provided via the GEOLAND2 project
123 (www.gmes-geoland.info), which oversees the generation of products derived from satellite data,
124 providing information on a wide range of variables including LAI. GMES is a European
125 contribution to GEOSS, the Global Earth Observing System of Systems (European Commission,
126 n.d.). The Sentinels are a series of satellites being developed by the European Space Agency that are
127 specifically designed to address the space observation requirements of GMES. There are five
128 Sentinel missions, each of which will consist of a pair of satellites (for details see Aschbacher et al.,

2012 and dedicated Sentinel mission papers, all this RSE issue). This paper is primarily concerned with methods for the retrieval of biophysical parameters of terrestrial ecosystems, including LAI, from instruments at arbitrary spatial resolutions, sun-sensor geometries and optical wavelengths. Consequently the techniques described here are directly relevant to Sentinels 2 and 3 missions. Sentinel 2 has a medium resolution multispectral imager (MSI) in the optical domain with 4 bands at a 10m resolution, 6 bands at 20m and 3 bands at 60m. These 13 spectral channels (Table 1) are distributed in the visible and near infrared and shortwave infrared regions. The Ocean Land Color Instrument (OLCI) instrument on board the Sentinel 3 platform is a coarser (circa 500m) resolution instrument, similar to MERIS that is designed for global monitoring applications. In principle the system described in this paper could also be extended to other wavelength domains and consequently be used to integrate data from the entire suite of EO missions.

140

141 TABLE 1 ABOUT HERE

142

An additional context for this paper is the growing interest in the application of wider constellations of satellites for environmental and disaster monitoring. A manifestation of this is the NASA A-train (NASA, 2010), which is a formation of complementary satellites and sensors taking observations at close to the same time. Other examples include relatively low cost satellites and instruments with a suite of similar instruments flying in formation to provide global daily viewing opportunities at mid-resolution (10-30m), for example the Disaster Monitoring Constellation (DMC) (DMCII, 2010). The concept can potentially be applied to more heterogeneous systems, such as the ‘virtual constellation’ for Land Surface Imaging (LSI) concept promoted by the Committee on Earth Observation Satellites (CEOS) to optimise benefits from land remote sensing systems (CEOS, 2011a). There are clear benefits for monitoring frequency if data from a wider range of sensors are available, but the more heterogeneous the set of sensors (in terms of spatial resolution and wavelength domains) the more important it is to formalize appropriate methods to optimally merge

information from these sources.

1.2 Optimal estimation

The remote sensing inverse problem described above can be phrased as an optimal estimation problem, requiring an estimate of a distribution around the minimum of some function of an observation residual vector, such as an ℓ^2 -norm. Our assimilation system is based on the joint inversion approach of (Tarantola, 2005) and is most conveniently formulated in what is often called a Bayesian context (Enting, 2002), which means that each piece of information (including any prior information on the state variables) is represented by a probability density function (PDF). Combining this information yields an *a posteriori* PDF for the parameters, which is the result/solution of the assimilation problem. If all of these PDFs are Gaussian and the models involved not too non-linear (potentially after a transformation) then the posterior parameter PDF can also be approximated by a Gaussian:

$$\rho(x) = \exp(-J(x))$$

which is the maximum likelihood estimate of the state variables x , thus the minimum of a cost function which takes the form:

$$J(x) = \sum_i J_i(x) \tag{1}$$

where $J_i(x)$ is a cost function expressing a constraint i , a member of some set of constraints.

Much of the earlier literature on estimating x for vegetation monitoring from a physical basis concentrated on exploring options in numerical minimisation approaches (see e.g. the review by

180 Kimes et al. (2000)) based almost entirely on using a single cost function $J_{obs}(x)$ expressing a
 181 mismatch between EO data and the prediction of an observation operator $H(x)$ (a radiative transfer
 182 model). The optimisation methods explored include, but are not limited to, downhill simplex
 183 (Privette et al., 1994), gradient methods (Gill et al., 1981; Liang and Strahler, 2002), neural
 184 networks, look-up tables and genetic algorithms (GA) (Combal et al., 2003; Myneni et al., 1995;
 185 Weiss et al., 2000). Although appropriate optimisation strategies and computer implementations
 186 have been around for some time that make use of J_{obs} , the gradient of J_{obs} with respect to x , in
 187 locating the minimum, they have not been widely used in terrestrial EO monitoring, primarily
 188 because of the perceived computational cost and numerical issues if finite difference methods are
 189 used to estimate J_{obs} , and more particularly because it is no trivial job to differentiate radiative
 190 transfer models. The advent of automatic differentiation (AD) methods and tools such as TAF (e.g.
 191 Giering and Kaminski, 1998, Lavergne et al., 2007) or TAPENADE (e.g. Qin et al., 2007) means
 192 that calculating J_{obs} for radiative transfer or other models is now quite feasible at computational
 193 costs not greatly dissimilar to the calculation of J_{obs} . The approach has first been applied to rather
 194 simple RT models such as RPV (Lavergne et al., 2007) and a two-stream model (Pinty et al., 2007;
 195 Clerici et al., 2010), but this is equally appropriate for more complex models as we show here. The
 196 ability to make rapid, exact calculation of the gradient vector not only widens the choice of
 197 algorithms that might be used to minimise the cost function, but also provides a route for potentially
 198 faster state vector estimation, and perhaps most importantly allows larger dimensioned problems to
 199 be tackled. Qin et al. (2008) were perhaps the first to apply AD to more complex RT models
 200 (MCRM of Kuusk (1995)) using a combination of GA and a cost function-based method using J_{obs}
 201 in the region of a trust region derived from the GA. In this case 7 members of the (dimension 14)
 202 state vector are estimated, but only at a single point in time. Results are not shown for parameters
 203 other than LAI, and no detailed consideration of uncertainty is included, but the ability to use AD in
 204 such scenarios is clearly demonstrated.

205

206 Data producers and users generally have little influence over control variables to the estimation
207 problem, as satellite sensors and missions are usually designed to serve (or are used to serve)
208 multiple purposes, and involve compromises in sensor design and orbits. Any one sensor (and the
209 resultant set of control variables entailed) then will tend to be sub-optimal for a task as specific as
210 vegetation monitoring. Inevitably this results in individual EO data sources having information
211 content that is too low to provide accurate retrievals of the entire state vector space. Some
212 parameters may never be completely retrievable on the basis of observation alone, especially where
213 there is equifinality between two or more parameters over the domain of the observed data, that is,
214 when the same model state can be reached by different combinations of state variables. See for
215 example (Beven, 2006) for an overview of this issue or Lewis and Disney (2007) for an attempt at
216 explaining mechanisms impacting this in canopy radiative transfer. The core of the issue is that the
217 observations only refer to a subspace of the unknown state variable space. In this case, no
218 information on some directions in state space can be gained from the observations, and their values
219 will have to be constrained using for example, prior information. Such problems are described as
220 being ill-posed. As an example, consider the often-desired goal of tracking the temporal evolution
221 of some parameter of interest such as LAI, to provide information on phenology. Inverting a model
222 on a daily basis where there may only be a small number of observations, or none at all, is typically
223 not possible as a single observation does not have enough information to constrain all of the state
224 vectors of typical radiative transfer models. This has been solved implicitly in the production of
225 many current EO data products by assuming the model parameters to be constant over some time
226 interval, and many of the ancillary parameters such as those governing leaf and soil properties are
227 simply assumed known (and fixed as is the case when using VIs). Assumptions such as temporal
228 invariance or knowledge of ancillary variables are pragmatic responses to the remote sensing
229 problem being ill-posed, but it is better if possible to seek less *ad hoc* methods for constraining our
230 estimate, especially if we wish to estimate uncertainty in the product.

231

232 A mechanism that provides scope for dealing with such problems is the suite of tools that are
233 collectively referred to as 'Data Assimilation' (DA). There is no strict definition as to what
234 constitutes DA but it is taken here to mean the statistically optimal merging of data and models.
235 Optimality, in this sense, implies the need to take into account uncertainties in all parts of the
236 system.

237

238 **1.3 Data Assimilation**

239 Data assimilation can be seen as mechanism for combining models and data. The defining feature of
240 DA, at least by the definition provided in this paper, is that it enables the use of additional
241 assumptions to make parameter estimation viable in situations that exhibit ill-posedness. In essence,
242 we have a mechanism through equation 1 to combine multiple constraints. An example of this that
243 has long been used either explicitly or implicitly in the inference of land surface parameters from
244 EO is constraint via *a priori* estimates of parameter values or ranges (or more generally,
245 distributions). What DA specifically brings to bear on the problem is a dynamic model of parameter
246 evolution in space and/or time.

247

248 Early examples of data assimilation systems are those used to improve short-range weather
249 predictions from meteorological models (Ghil and Malanotte-Rizzoli, 1991). In these systems the
250 number of state variables is typically huge, often greater than 10^6 , because of the large number of
251 interconnected sub-domains used to represent the atmosphere in a 3D grid. The number of
252 observations available is typically several orders of magnitude less than this, and in consequence
253 the problem is ill-posed. However, including a constraint that the final solution should not diverge
254 too far from an *a priori* estimate (typically supplied by a previous model run) tends to result in a
255 tractable solution. The schemes used for these problems are referred to as 'variational', being based
256 in the field of mathematics dealing with the calculus of variations, and are closely related to the DA
257 system described in this paper. A 'strong constraint' variational DA system assumes that the

underlying process model prescribing the state vector evolution is correct (i.e. there is a model trajectory that matches the observations). In this case it is generally only the initial state of the system that is estimated by the DA procedure, but this approach can also be used to calibrate models (i.e., to optimise estimates of model process parameters) (Knorr et al., 2010). If the state vector is allowed to deviate from the model predictions then this is referred to as a 'weak constraint' DA system (Zupanski, 1997). It is this latter type that is used here and is discussed more completely in later sections.

265

We note that these systems have been exploited to estimate LAI from MODIS data by making use of a coupled phenology temporal trajectory model with a radiative transfer model (Xiao et al. 2009; Xiao et al. 2011). MODIS LAI is assimilated into a crop model using a variational technique in Fang et al. (2008a). The variational approach is shown to help in retrieving surface fluxes in Oliosio et al. (2005) and Qin et al. (2007), and has found wide application in the hydrological literature (see for example McLaughlin, (2002)).

272

Another related set of techniques in the DA canon may be called sequential methods. The most widely-known and widely-used example of these is the Kalman Filter. Sequential methods generally only consider observations at a single time step and adjust the model state vector at that time by an amount proportional to the differences between the observations and the predictions of those observations using that model state. Using a variant of the Kalman Filter, known as the Ensemble Kalman Filter (Evensen, 2003), Quaife et al. (2008) demonstrated the assimilation of satellite reflectance data into a simple ecosystem model using an RT model as observation operator. Other efforts have used these techniques to assimilate e.g. snow data (Slater and Clark, 2009) or MODIS-derived LAI into a phenology model (Stöckli et al., 2008). The related technique of particle filtering has been used to assimilate microwave temperature in order to infer soil moisture dynamics in Qin et al. (2009).

284

285 The Earth Observation Land Data Assimilation System (EO-LDAS) study funded by ESA aims at
286 supporting the generation of a generic land data assimilation system by using the full information
287 content provided by observations from satellite constellations. Such a system, in eventual
288 operational form, is intended primarily to improve the quality and consistency of land surface
289 products generated from multi-sensor EO data. The project is focussed on developing a generic
290 scheme and software prototyping for use with medium to mid spatial resolution (in the range 10m –
291 500m) optical data. The principal design concept is to allow integration of data from different
292 satellites observing the surface of the earth at different sun-sensor geometries, wavebands and
293 spatial scales, such as that supplied by Sentinels 2 and 3, in a physically consistent manner, and to
294 provide information on the state of the surfaces with well-quantified estimates of uncertainty. It also
295 demonstrates the idea that predictions based on data from one sensor can be made from a DA
296 system driven by observations from another, a concept that could potentially be used to aid
297 vicarious sensor calibration.

298

299 **2 The EO-LDAS prototype**

300 **2.1 The EO-LDAS Scheme**

301 The EO-LDAS prototype is an initial version of the scheme, designed to
302 carry out a core set of DA functions. In particular, in the *scheme*, it performs an atmospheric
303 correction of images to top-of-canopy reflectance, retrieves canopy state variables using surface
304 reflectance data and a constraint model and simulates top-of-atmosphere radiance or reflectance for
305 a given surface and atmosphere. This preserves the essential features of a more comprehensive
306 system (incorporating a fuller coupling between the surface and atmosphere), while allowing
307 development and further study of the most important elements - the observation operators and the
308 assimilation techniques.

309

310 To simplify the prototype, we have assumed a large length scale for variations in atmospheric
311 scattering properties, and a very short length scale for surface variability. With these assumptions,
312 we can correct an image (or sub-image) with a single set of atmospheric state variables, use
313 reflectance data in a multi-temporal assimilation on a cell-by-cell-basis, and simulate a top-of-
314 atmosphere radiance field using the same atmosphere for each of a set of model grid cells. This
315 process can be iterated to achieve the surface-atmosphere coupling. To relax either constraint
316 would mean we have to deal with the inversion of a coupled surface-atmosphere problem over a
317 large number of cells, which would require considerable computing resources, both in terms of
318 memory (for the covariance structures involved) and the time needed to carry out the actual
319 inversion, without necessarily improving our ability to monitor the land surface. A tutorial guide
320 explaining the functionality and use of the prototype system is available online¹.

321

322 The DA system can be considered to have two main components: (i) a set of constraints, expressed
323 via equation 1; (ii) an assimilation algorithm, i.e. a way to apply the constraints to achieve the
324 optimal estimate of the state vector. The set of constraints in EO-LDAS involves: (i) an
325 observational constraint $J_{obs}(x)$, requiring data (from EO or ground measurements) and a model for
326 translating from state space to observation space (the observation operator); (ii) a dynamic model
327 constraint $J_{model}(x)$, conditioning the temporal (and/or spatial) evolution of the state vector; (iii)
328 physical or empirical bounds and/or distribution constraints $J_{prior}(x)$ to the state vector elements;
329 Thus, in EO-LDAS, equation 1 becomes:

330

331
$$J(x) = J_{obs}(x) + J_{prior}(x) + J_{model}(x)$$

332

333 Each of these constraints has associated with it an error model. In the following sections, we

¹ <http://www2.geog.ucl.ac.uk/~plewis/eoldas/>

334 describe the set of constraints and the DA algorithm. We stress that in the text below, we use the
 335 symbol x to refer to the set of state variables that we wish to estimate. In EO-LDAS this essentially
 336 means a representation of the state at each sample points in time (and/or space) that we consider.
 337 So, for example if we were trying to estimate Leaf Area Index and leaf Chlorophyll content at one
 338 location for every day of the year, we would have a state vector with 361x2 elements. In addition,
 339 EO-LDAS has the capacity to augment this state vector with ‘static’ state representations (some
 340 term affecting one or more of the constraints that we wish to be considered constant in space/time).

341

342 **2.2 Observational Constraint**

343 Given the EO context of this system, at least one of these constraints should be based on
 344 observations. The cost function is generally weighted for observation and observation operator
 345 uncertainty and correlation (assumed in EO-LDAS Gaussian and described by C_{obs}):

346

$$347 \quad J_{obs}(x) = \frac{1}{2} (R - H(x))^T C_{obs}^{-1} (R - H(x)) \quad (2)$$

348

349 where T denotes the transpose operator. This is the penalisation associated with differences between
 350 the predicted and observed reflectance values. The covariance matrix C_{obs} describes the uncertainty
 351 in the observations (and also formally, in the observation operator). As noted, the purpose of the
 352 observation operator $H(x)$ is to translate information from the state space to that of the
 353 observations, and is in practice a radiative transfer model. For ease of implementation (mainly
 354 involving spectral sampling issues), when different sensor types are used in EO-LDAS, a set of
 355 $J_{obs}(x)$ terms is developed, with one for each sensor type.

356

357 There have been many attempts to create observation operators $H(x)$, varying in complexity,
 358 accuracy and computational cost. Goel (1988) provides a review of most of the concepts for

359 radiative transfer model developed for reflectance from vegetation canopies at optical wavelengths
360 (see also (Goel and Thompson, 2000), with (Tha Paw U, 1992) covering related materials for
361 thermal emitted radiation and (Fung and Chen, 2010) for the microwave domain. Some updates and
362 model intercomparisons are provided by Sobrino et al. (2005) (thermal) and Widlowski et al.,
363 (2007) (optical). The focus in this paper, and in the prototype EO-LDAS is on the use of optical
364 sensor data, but the approach outlined here is easily adapted for use in other wavelength domains.

365

366 In a similar way, atmospheric properties, such as aerosol optical depth and water vapour content,
367 need to be accounted to obtain accurate estimates of surface properties. This can be achieved by
368 coupling the surface model with an atmospheric model, and solving for both the surface and
369 atmosphere parameters simultaneously (Verhoef and Bach, 2003). Some (probably most)
370 approaches to surface interpretation use surface reflectance that has already been ‘corrected’ for
371 atmospheric effects (Vermote et al., 2002), but a full decoupling of the problem, at optical
372 wavelengths at least, cannot be achieved without knowledge of the surface Bidirectional
373 Reflectance Distribution Function (BRDF) (Lyapustin and Knyazikhin, 2001; Lyapustin et al. 2006)
374 (or at least a normalised form of this) (Vermote et al., 1997).

375

376 The observation operator we use in this paper is developed from the original semi-discrete model of
377 Gobron et al., (1997). It has a state vector describing canopy architecture and three spectral terms,
378 although these are all defined as functions of other parameters as described below (Table 2). The
379 soil reflectance is assumed Lambertian in the model, although it could be adapted to incorporate a
380 soil directional reflectance model. As stated here then, the (canopy-soil) model estimates the
381 directional reflectance factor at a set of viewing and illumination angles for a given narrow
382 waveband. Since the model must be capable of predicting the reflectance at arbitrary (solar
383 reflective) wavelengths, spectral models are incorporated in the code to predict the soil
384 (Lambertian) reflectance and leaf (bi-Lambertian) reflectance and transmittance. Since model

385 derivatives are required, we use for simplicity here: (i) the linear soil reflectance model of Price
386 (1990); and (ii) an approximation to the PROSPECT leaf reflectance/transmittance model of (Féret
387 et al., 2008), being a minor modification of the model of (Jacquemoud and Baret, 1990). The
388 approximation was developed for possible processing speed enhancements, but is identical in form
389 to PROSPECT if the parameter N (table 2) is 1, and very close to the original model over the range
390 of N 0.8 to 2.5.

391

392 The soil spectral model of Price (1990) characterises a given soil at field capacity as a linear
393 combination of Empirical Orthogonal Functions (EOFs) based on a database of moist (field
394 capacity) soil spectra. Four EOFs are found to account for 99.6% of the cumulative variance of all
395 the soils considered, so, as is usual, we use up to four terms in this implementation. Parameter
396 ranges in Table 2 come from (Price, 1990), figures 11-13.

397

398 TABLE 2 ABOUT HERE

399 TABLE 3 ABOUT HERE

400

401 The leaf angle distribution is categorised in the model of Gobron et al., (1997) and so not set by the
402 assimilation procedure (i.e. it must be pre-defined or the different categories assessed separately:
403 this could ultimately be improved using a continuous description). The assimilation scheme can
404 provide estimates of the remaining (12) state variables for each time period modelled. Following
405 (Weiss et al., 2000) we apply approximate linearization functions to some of the terms (Table 3).
406 The reasons this is appropriate here are: (i) they better condition the problem for optimisation; (ii)
407 the assumptions of Gaussian distributions of errors are more appropriate in this case.

408

409 Differentiated versions of the observational cost are required to enable the use of efficient gradient
410 descent minimisation routines, so we can benefit from access to $J_{obs}'(x)$, the derivative of $J_{obs}(x)$

411 with respect to x . This is:

412

$$413 \quad J_{obs}^{\mathbb{C}}(x) = -H^{\mathbb{C}}(x)^T C_{obs}^{-1} (R - H(x)) \quad (3)$$

414

415 where $H^{\mathbb{C}}(x)$ is the derivative of $H(x)$ with respect to x . An adjoint code of the cost function for
416 the semi-discrete model, i.e. code for direct calculation of $J_{obs}^{\mathbb{C}}(x)$ that avoids the need for explicit
417 calculation and storage of $H^{\mathbb{C}}(x)$, was generated from the source code of the model by the
418 automatic differentiation tool TAF (Giering and Kaminski, 1998). The adjoint code implements the
419 chain rule of differentiation in the so-called reverse mode. It provides the gradient information that
420 is accurate up to machine precision at a computational cost that is not greatly dependent of the
421 length of the gradient vector and well below that of the multiple runs of the semi-discrete model
422 that would be required for a finite difference estimate.

423

424 We obtain an estimate of the posterior uncertainty through consideration of the curvature at the
425 global minimum in state space. This is provided by the inverse of the sum of the constraint
426 Hessians, the Hessian for this constraint being $J_{obs}^{\mathbb{C}}(x)$:

427

$$428 \quad J_{obs}^{\mathbb{C}}(x) = H^{\mathbb{C}}(x)^T C_{obs}^{-1} H^{\mathbb{C}}(x) - H^{\mathbb{C}}(x)^T C_{obs}^{-1} (R - H(x)) \quad (4)$$

429

430 Although it should be possible to develop a Hessian code in much the same way as done for the first
431 derivative, that has not yet been done within EOLDAS, so a linear approximation to the Hessian is
432 achieved, using finite differences. As we will see below, the algorithm used to perform the
433 optimisation is iterative, but the potentially high cost of using finite differences for the Hessian is
434 unimportant in this sense, as it only has a role in estimating the posterior uncertainties.

435

2.3 Process model constraint

The EO-LDAS prototype is designed to allow the user to interface their own constraints, so long as they provide code to calculate the cost function and its first and second order derivatives. This allows a mechanism whereby (bio)physical process models can be used to constrain the solution and or estimates of the variables controlling those models can be developed. The focus of the prototype software and that of this paper are on understanding how to use DA concepts to improve estimates of biophysical variables from EO data, rather than to test specific process models however. For this reason, we have currently only implemented a linear process model in the system:

$$M(x) = Ax + b \quad (5)$$

where A and b are a matrix and vector respectively. One advantage of designing the prototype system in this manner is that it provides a flexible framework for changing the underlying model. Unlike in a sequential system, this formulation directly allows for any model state vector element to be linked to any other, since x here contains the state representation at all sample times (spaces), so different time/space scales can be readily incorporated. The cost function associated with this process model then is:

$$J_{model}(x) = \frac{1}{2}(x - M(x))^T C_{model}^{-1} (x - M(x)) = \frac{1}{2}((I - A)x - b)^T C_{model}^{-1} ((I - A)x - b) \quad (6)$$

where I is the identity operator. $J_{model}(x)$ is the cost incurred by departure of the model state from that predicted by an underlying process model. An interpretation of A is as the model derivative. The model uncertainty matrix C_{model} therefore expresses the uncertainty in this derivative, including any inherent uncertainty in the process model. In such a case, it might often be pragmatic to specify only diagonal terms in C_{model} as further details of model structure are often difficult to obtain. In

any case, we can see that EO-LDAS could be interfaced to a process model such as the Carbon Flux model DALEC used by Quaife et al. (2008) or any other for which the derivative might be obtained (e.g. using AD) by augmenting the state vector x by any terms that we might wish to drive the model.

Whilst the EO-LDAS scheme allows for linking to ‘biophysical’ or other process models, that is not the main focus of the prototype. Indeed, there are many cases, for instance when conducting a comparison of information derived from EO data and some biophysical model trajectory, when it may be undesirable to directly incorporate a detailed process model. Further, and perhaps more importantly, a fundamental requirement of the EO-LDAS system is that the state vector, x , contains at least the parameters of the observation operator $H(x)$ for every point in time (and/or space), and many of these may not be provided by a biophysical process model designed, for example, to estimate total Carbon fluxes. We should see the matrix A (and if needed, the vector b) then as a much more general interface to ‘process modelling’ within an optimal estimation environment.

We can for example consider the benefits of approaches such as Twomey-Tikhonov regularisation or variations around this theme (Rodgers, 2000). Examples of this that we explore further below are first and second order difference constraints. In essence these improve the conditioning of the inverse problem by smoothing or regularising the solution, which comes about because they constrain derivatives (first or second order here) to be zero. In a weak constraint DA system such as that used here, the model is not strictly enforced (this would be clearly undesirable in these derivative constraints) but rather the degree of smoothness in the outcome is traded off against the other factors in $J(x)$ through the model uncertainty matrix. In other words, the cost function will penalise temporal trajectories of parameters that are not flat, but this is ‘balanced’ with a goodness of fit to the observations and departure from the prior estimate. In practice this constrains the solution toward a smooth evolution by minimising the high frequency components of the temporal

parameter trajectory. A similar approach has been taken by Quaife and Lewis (2010) for linear observation operators. Viewing this form of solution as a combination of state variable estimation and filtering, we note that the filter characteristics are controlled by the nature of matrices A and C_{model} , the former controlling the cut-off frequency of the filter and the latter, if simply diagonal, controlling the degree of dampening of the unwanted high frequencies. In this context, we can consider b a bias term, which we set to zero. In this case:

$$J_{model}(x) = \frac{1}{2} (Dx)^T C_{model}^{-1} (Dx)$$

where $D = (I - A)$. The derivatives of this are: $J'_{model}(x) = D^T C_{model}^{-1} Dx$ and $J''_{model}(x) = D^T C_{model}^{-1} D$. To achieve Twomey-Tikhonov regularisation then, which we view as an empirical process model, D here becomes simply a (N^{th} order) differential operator (Quaife and Lewis, 2010). In many situations, we must assume the uncertainty in this empirical constraint unknown. The minimum error model then is a constant value for which we can use a scalar term g :

$$J_{model}(x) = \frac{g^2}{2} x^T (D^T D) x \tag{7}$$

We can interpret g as a ‘smoothness term (or g^{-1} as a roughness term) that controls the weighting of the derivative (model) constraint with respect to the other constraints. It is worthwhile at this point trying to relate this back to the discussions on process models. This is most readily achieved by considering a first order derivative constraint. If applied at lag 1 day for a temporal constraint, we can interpret this as an expectation that the state vector tomorrow will be the same as today (i.e. the derivative is zero). If we want to relate this to equivalent sequential methods, we can say that this is a zero-order process model. The term g^{-1} then can be interpreted as uncertainty (phrased as

511 standard deviation) in this model, or alternatively as the growth in uncertainty over a one day
512 period. Similar interpretations apply for other derivative constraints: a second order derivative
513 constraint is equivalent to a first order process model. Equation 5 then is a viable empirical process
514 model constraint, but we have yet to tackle the fact that the smoothness g is unknown. We also note
515 that if we use a scalar for g , we are assuming the same smoothness for all state variables at all times
516 (places).

517

518 An option that arises with dynamic models (where we are making connections between elements of
519 the state vector at different times (places) is what to do about boundary conditions. Even with a
520 simple differential model this needs consideration in forming the D matrix. Among the various
521 options, especially when dealing with annual or multi-annual datasets, an attractive one is to assume
522 periodic boundary conditions, and that is done here. This means that in calculating D at the end of
523 the year (edge of the matrix) we perform the digital differential with state elements from the
524 beginning of the year.

525

526 It is generally found (e.g. Twomey (2002)) that quite a broad range of model uncertainty
527 (smoothness) estimates can provide an acceptable solution, so we do not expect the results to be
528 overly-sensitive to the choice of this ‘hyper-parameter’. We could make a rough guess at the model
529 uncertainty, but that is likely to be unsatisfactory in the general case. If we under-estimate it by too
530 much, we can over-dampen most of the state vector. Equally, if we greatly over-estimate the model
531 uncertainty, the impact of the temporal constraints is minimal: in the extreme, an infinite model
532 uncertainty (zero smoothness) leads to a solution without model constraint. Whilst there are several
533 strategies that can be employed to estimate the model uncertainties (hyper-parameters), perhaps the
534 most fruitful in the context of EO-LDAS is running a cross-validation exercise. The idea is that an
535 independent dataset is used to test the robustness of the solution for a particular value of the hyper-
536 parameters. An optimal estimate of the hyper-parameters (or distribution thereof) can be obtained

by minimising a cost function with the independent observations. This can be achieved with a subset of observations to test a solution obtained from the rest of the dataset, a strategy that when repeated over different subsets becomes known as generalised cross validation becomes known as generalised cross validation (Wahba, 1990, Eilers, 2003 and Lubansky et al., 2006).. Alternatively, we might use data from an independent sensor, although accurate absolute calibration between the sensors is needed for that.

543

544 **2.4 Prior Constraint**

An additional constraint mechanism is implemented in EO-LDAS, that we term a prior constraint. Its role, via the cost function $J_{prior}(x)$ is to impose a penalty for deviation from some previously defined state, x_{prior} :

548

$$549 \quad J_{prior}(x) = \frac{1}{2} (x - x_{prior})^T C_{prior}^{-1} (x - x_{prior}) \quad (8)$$

550

where C_{prior} expresses the uncertainty of the prior model state, a measure of our belief in the prior estimates, x_{prior} . The derivatives of this cost function are $J_{prior}'(x) = C_{prior}^{-1} (x - x_{prior})$; $J_{prior}''(x) = C_{prior}^{-1}$. A comparison of equations 6 and 8 shows that this is really just another form of model constraint, with $M(x) = x_{prior}$, which can be achieved with the existing model constraint by setting $b = x_{prior}$. In practice, this allows us to enforce a prior belief in the distribution and range of the state vector elements (e.g. a climatology or physical or otherwise known ‘reasonable’ distributions), although only Gaussian distributions can be considered.

558

559 **2.5 DA algorithm**

560 The various constraints discussed above provide the cost function in equation 1 through their

561 summation. This also applies to the derivatives $J\ell(x)$ and $J\mathbb{C}(x)$. The cost function $J(x)$ is
562 minimised using a gradient descent method (i.e. using $J\ell(x)$). Bounds are applied as a final
563 constraint to the solution, to ensure that the state vector remains within physical limits. These can be
564 altered by the user for any particular run of the system via a configuration file or command line
565 interface. In the EO-LDAS prototype we use the limited memory Broyden-Fletcher-Goldfarb-
566 Shanno (L-BFGS-B) algorithm described in (Byrd et al., 1995; Zhu et al., 1997). In principle,
567 however, a number of different gradient descent algorithms could be used. The L-BFGS-B was
568 selected for its efficient memory handling for high dimensional problems and the fact that it can
569 optimise over a bounded domain, which is appropriate for this problem.

570

571 The algorithm then is quite straightforward: (i) read in configuration information and observations;
572 (ii) provide an initial estimate of all state vector elements that we wish to estimate; (iii) iterate
573 within the optimisation routine until convergence is reached (or using other criteria) to estimate the
574 state vector; (iv) calculate the Hessian and then its inverse to provide the posterior covariance
575 matrix, the estimate of uncertainty.

576

577 It is instructive to consider the contribution of these three terms in the estimates of Hessian matrix.
578 The observational term can be ill-conditioned if the observations exhibit little sensitivity to some or
579 all of the state variables, for example due to poor combinations of spectral and/or angular sampling.
580 The addition of the prior and dynamic model terms then results in improved conditioning of $J\mathbb{C}(x)$,
581 as these extra terms compensate for the lack of observation sensitivity to some of the state variables.
582 They also provide the ability to interpolate (i.e. rely more on the process model) between where we
583 have observations. Importantly, the uncertainties are tracked throughout this process, so when e.g.
584 interpolating over large gaps, we get the expected increase in uncertainty.

585

586 The DA system developed here can be viewed an extension of the methodologies that have been

587 applied to inverting radiative transfer models by minimising a cost function. The addition of a linear
588 dynamic model therefore only adds a handful of extra parameters to the problem (namely, the nature
589 of the dynamic model itself and the associated covariance matrix, C_{model} , which may be simply
590 diagonal). This is in a marked contrast with similar methodologies that either use a long time series
591 of data for inverting one single parameter (in the case of inverting LAI as in (Fang et al. 2008b;
592 Xiao et al. 2009; Xiao et al. 2011)). The temporal smoothness constraint is in itself an important
593 feature, which is usually performed as a post-processing step after the parameter retrieval (Lu et al.
594 2007).

595

596 **3. Experimentation**

597 We present a series of experiments to demonstrate the operation of the EO-LDAS prototype and to
598 explore the sorts of capabilities such a system could provide with data from the Sentinel-2 MSI
599 sensor (see table 1a for waveband information for Sentinel-2 MSI). The experiments use synthetic
600 data for observations i.e. are derived from running the observation operator for a given state vector
601 for what we suppose to be typical Sentinel-2 scenarios over one calendar year. We simulate top hat
602 function bandpass functions (1 nm sampling) according to the information in Table 1 (see also
603 Drusch et al., 2012, this issue). The main aim of the experiments is to determine the improvement,
604 in terms of reduced uncertainty, in biophysical parameter estimation that might be obtained by
605 applying the EO-LDAS prototype for such scenarios. A subsidiary aim is to demonstrate the
606 capability of the DA system to make predictions of data from a sensor not used in the DA process.
607 Here, we do this by using the state vector estimates derived from the DA with synthetic MSI data,
608 and make predictions of what a SPOT-5-like instrument would view (described below). These data
609 are used in a cross-validation exercise within the experiments.

610

611 **3.1. Experimental setup**

612 In these experiments, we control the time trajectory of a subset of model parameters according to

the functions given in Table 4, where t is the relative day of year (DOY) i.e. DOY normalised by 365. All other parameters take their default values given in Table 2. The functions for LAI and chlorophyll broadly mimic typical trajectories of these terms for crops: for LAI, a flat initial period, followed by a rise to maximum LAI and then a symmetric decrease; for Chlorophyll, a linear rise and decrease. The more arbitrary functions used for the soil brightness term s_1 we include to mimic rather broad variations over the year that might be supposed to be responses to soil moisture. A similar function is used here for leaf water, with a time lag of 36.5 days. The quite large variation of these two latter terms is intended primarily to allow the operation of the data assimilation scheme to be explored over a wide range of conditions, rather than to too closely mimic some particular situation. In that context, the rather large time lag between soil brightness variation and leaf water content is unrealistic, but a larger phase between these terms should test the system to a greater extent than having all parameters following similar trajectories. Although the full set of state vector elements is 13 for each time sample, we attempt to retrieve only the 6 elements (no 1, 4, 6, 7, 8, 9 in table 2) (per time sample) that we vary in these experiments, i.e. we assume the remaining elements fixed and known. This is partly to reduce the computational time required for the DA and more broadly because we believe it is sufficient to demonstrate the principles underlying the DA method. It is quite feasible to permit an estimation of 12 of the 13 elements (not the categorical variable directly through this method) but this is not the purpose of this exercise, and (arbitrary) variations in these additional terms would need to be defined to achieve this.

632

633 TABLE 4 ABOUT HERE

634

To approximate the Sentinel-2 MSI acquisition geometry (ESA, 2010), we assume one sample every 5 days (73 samples over the year), with a solar zenith angle corresponding to 10:30 local time at 50° N, random relative azimuth and random view zenith between 0° and 15°. Whilst these parameters do not provide a precise prediction of the likely MSI sampling and geometries, they are

639 close enough to develop an understanding of the likely behaviour of the data. The random azimuth,
640 for example, is clearly in error, but since the view zenith angle is so restricted, this will have very
641 little impact; the local time at 50° N will in reality be slightly later than the nominal equatorial
642 crossing time used here, but the details of the solar zenith angle are less important here than
643 inducing a typical variation over the year (32° to 76° here). The simulation of one sample every 5
644 days mimics close to the maximum sampling achievable by MSI on 2 Sentinel platforms.

645

646 Synthetic observations were also generated for a SPOT5 HRG-like instrument. This sensor has four
647 wavebands (500-590, 610-680, 790-890 and 1530-1750 nm) (CEOS, 2011b). We have assumed a
648 revisit period of 13 days (to be out of sync with the synthetic MSI observations), although the
649 differences are only up to two days from the MSI observations. The view zenith angle was limited
650 to +/-25 degrees from nadir, with a random azimuth and a local overpass time of 10.30. In total, 28
651 observations were available in this dataset.

652

653 Uncorrelated Gaussian noise is added to the observations as part of the data synthesis. We assume
654 the standard deviation of this to vary linearly from 0.008 at the shortest wavelength to 0.020 at the
655 longest, for both the MSI and SPOT-5 HRG. These values are broadly twice those claimed for
656 atmospheric correction of data from the NASA MODIS instrument (Roy et al., 2005). If an
657 atmospheric ‘correction’ were performed on the data, we would generally expect the uncertainty in
658 surface reflectance to be correlated across wavelengths, as e.g. an under-estimation of aerosol
659 optical thickness would likely give rise to an over-estimate in reflectance for the shorter wavelength
660 bands. Here, we have inflated the assumed (MODIS) uncertainties by a factor of two to take some
661 account of such likely correlation. This highlights one of the benefits of ultimately using a more
662 fully coupled surface-atmosphere observation operator, in that such features would fall naturally out
663 of the model formulation and random noise might be more reasonably assumed for top of
664 atmosphere radiance or reflectance. However, for the purposes of these experiments it is sufficient

665 to treat only the surface (canopy-soil) elements of the observation operator.

666

667 We term this simulation set ‘complete’ for the purposes of this paper, in that it expresses a rather
668 idealised situation where no clouds are present. A second synthetic observation set that we term
669 ‘cloudy’ (36 observations for MSI and 15 for SPOT-5 HRG) is derived from this, for which we have
670 removed 50% of the observations according to a correlated random function to mimic persistence of
671 cloud cover. This induces (‘cloud’) data gaps of up to 60 days (mean gap 10.3 days, standard
672 deviation 12.6 days for MSI).

673

674 As noted above, the cost function minimisation is achieved in EO-LDAS with the L-BFGS-B
675 algorithm. A bounded minimisation is performed within this code, with the limits specified on the
676 (transformed) state variables given in Table 2 (transformations in Table 3). Thus, all state variable
677 estimations below proceed with the prior knowledge of an upper and lower bound. There are several
678 convergence criteria that can be used with the L-BFGS-B, including an absolute threshold on the
679 cost function and a relative (per iteration) threshold. In all experiments, these are set to low values,
680 which means that more iterations might be employed than strictly necessary in any operational
681 context, but making sure that the global minimum (or very close to it) is reached in each estimation.
682 Because of the additional costs of processing full bandpass functions, all ‘initial’ processing is
683 performed using the median (1 nm) wavelength of each waveband. A ‘polishing’ step is then
684 performed to achieve convergence from this starting value, using the full bandpass sampling. The
685 effect of applying the full bandpass functions tends to be generally quite minor.

686

687 We have initially tested the system without observational noise and confirm that the scheme
688 retrieves the truth to within the bounds implied by the convergence criteria and machine precision.
689 Processing time for a single set of 73 time samples with MSI spectral sampling, solving for 6 state
690 vector elements for each day of the year (2190 in total), is currently several hours on a 3 GHz Intel

691 processor on a single core, but this is partially due to very stringent convergence criteria used whilst
692 testing the code and partially because this prototype implementation requires some significant
693 efforts in computer code optimisation.

694

695 In all experiments, we set the prior estimate of the state vector to the values shown in table 2, with
696 very large diagonal uncertainty terms (8). This effectively removes the prior constraint from
697 consideration in these experiments, as we wish to conduct experiments based only on model and
698 observational constraints here.

699

700 In the following sections, we examine the result of applying the weak constraint variational data
701 assimilation approach described above to the synthetic dataset. For all cases, we assume that the
702 uncertainty in the observations is known and that it is Gaussian and uncorrelated between
703 wavebands and between dates. In the first case (3.2), we solve for state vector estimates assuming
704 no dynamic model constraint other than the weak prior (standard deviation 8). This acts as a
705 baseline for further experiments. In the second case (3.3) we assume that model uncertainty g is
706 unknown and attempt to solve for it and the state vector for each day in the year with a form of
707 cross-validation exercise using the SPOT-5 HRV synthetic observations. The ‘true’ values of g for
708 individual state vector elements are shown in Table 5. The DA is performed with the ‘complete’ (i.e.
709 5-day sampling MSI) dataset in that case. Finally, we repeat that experiment for the ‘cloudy’ dataset
710 (3.4).

711

712 TABLE 5 ABOUT HERE

713

714 Graphical results (figures 1-2) are presented as untransformed biophysical variables (i.e. LAI, C_{ab} ,
715 C_w , C_{dm} , N and s_l), showing: the ‘true’ (‘original’) state vector (dashed line); circles and error bars
716 (shaded region) shows mean and 95% credible interval bounds (at plus/minus 1.96 standard

717 deviations). We will term 1.96 standard deviations ‘uncertainty’ for the remainder of the paper,
718 unless the statement is otherwise qualified. The uncertainty bounds are slightly larger for the upper
719 limits than for the lower limits (other than for N and s_1) due to the nature of the transformations
720 used in the approximate linearization (table 3). Tabular results for the experiments (tables 9-12) are
721 expressed in transformed parameter space, as that is the space in which the state vector is inferred
722 and in which the Gaussian statistics derived are most natural.

723

724 3.2 Baseline estimates

725 We first produce a baseline estimate of the six state variables over the 73 time periods in the year,
726 assuming no constraint to the solution other than the bounds noted above, the (noisy) observations,
727 knowledge of the uncertainty in the observations, and the weak prior constraint.

728

729 The results for the baseline experiment are produced using the EO-LDAS system with each
730 observation set (i.e. all wavebands, but only one angular sample) independently. The algorithm
731 requires an initial guess of the state vector and iterates to its final estimate. The initial estimate of
732 the state vector in each case and all subsequent estimates is taken as the value used in the prior
733 constraint.

734

735 FIGURE 1 ABOUT HERE

736

737 In figure 1, the column titled ‘single obs inversion’ shows the results of this state vector estimate for
738 the six parameters that are varied, transformed back to their biophysical meanings (through the
739 inverse of the functions in table 3). The sub-plots rows show results for the observation operator
740 parameters LAI, C_{ab} , C_w , C_{dm} , N and s_1 respectively. The uncertainty (average credible interval)
741 associated with each (transformed) parameter for the baseline experiment is given in table 6 (‘single
742 obs.’). Relating these uncertainties to the parameter ranges (table 4), we note that they are around

5% for TLAI, 10% for s_1 and TC_{ab} respectively for dates where there are observations, more than 20% for (transformed) leaf water and dry matter content and around 33% for N. We can suppose these then to be typical uncertainty values for MSI sampling (with the assumed noise characteristics). The cross correlation associated with these, illustrated in table 7 are highly variable from one sample to the next. The median values given show quite strong negative correlations between TLAI and TC_{ab} and TC_w but positive correlations with s_1 and TC_{dm} . The median s_1 shows negative correlations with all terms other than TLAI. Despite the fact that the average transformed LAI uncertainty is only around 5%, we can see in figure 1 that both the error and uncertainty can be rather high. Around peak LAI, results from individual samples vary by around LAI 2.5 and there is a general tendency to underestimate. The general trends of C_{ab} and C_w are discernable, but there is large variation and large uncertainty. The terms that are supposed to be constant here, C_{dm} and N depart significantly from their true state and the negative correlation is evident in the state trajectories around the central part of the year.

756

757 TABLE 6 ABOUT HERE

758 TABLE 7 ABOUT HERE

759

How then can we improve on this situation? The ways to reduce uncertainty are to have data with lower noise characteristics, to average or smooth in some way, or to add other constraints to the solution. In any realistic scenario, we have only limited control of the first of these. Averaging and smoothing then are the general pragmatic responses to such issues. If however this is performed *ad hoc* as a post processing step to any individual term (e.g. only LAI) this would not take account of the cross correlation in the uncertainties which can only give sub-optimal results.

766

In spite of these quite high levels of uncertainty (and correlation of uncertainty) for these estimates, there is clearly quite a strong correlation between the values of the state vector and its neighbours in

time. The general underlying patterns are apparent in the ‘complete’ scenario, although much of the (potentially important) detail will be lost in a more realistic ‘cloudy’ scenario. The enhancement of this temporal correlation effect and the suppression of the noise are at the heart of all regularisation approaches and the essence of weak constraint data assimilation. If we have some model (‘expectation’) of the temporal trajectory of the state vector, then we can use this to filter the unwanted noise. As noted above, this may be a model based on our understanding of radiation interception and biogeochemical cycling (e.g. Quaife et al., 2008) driven by some set of external (environmental) parameters, or it may simply be some parametric curve that we believe can mimic e.g. the phenological development of LAI. In either case, what DA aims to achieve is an optimal merging of such models (through the adjustment of the state vector or essentially a calibration of the parameters controlling the development of state in the model) and the observations. For land surface monitoring, there are several options for such models for LAI development as mentioned, and up to a point for some other state variables (e.g. soil moisture), but there is very little to guide information extraction on many other state variables that affect the observations (e.g. leaf chlorophyll concentration or dry matter). In such a case, we need to develop simple methods, within a DA framework. Fortunately, there are many to choose from, although as Twomey (2002) points out, the results are likely to be similar for most of these methods: indeed, it would be worrying if they were not.

787

788 **3.3 DA: Complete scenario**

Here, we apply first order and second order derivative constraints to the solution, but we expect the results to be broadly similar. In both cases, we need only supply some estimate of the uncertainty associated with these constraints through the smoothness term g to achieve a regularised solution to the state vector estimate. These constraints are applied by incorporating a model that, in the absence of any observations, would set the first (second) derivatives of the state variables to zero. Assuming that we apply the same (strength of) constraint to the whole time series, we need to supply an

795 estimate of the mean squared first (second) difference in the parameter values (true values in table
796 5). For the first (second) difference then, this can be thought of as an estimate of the uncertainty in a
797 zero-order (first-order) process model over one time step as noted above.

798

799 We use a form of cross-validation to estimate g . This is achieved with a synthetic dataset from an
800 alternative SPOT-5 HRG-like sensor. The core of the exercise then is a comparison between these
801 synthetic data (driven by the ‘true’ values of the state vector, plus random noise as above) and a
802 simulation of the same sensor wavebands and acquisition geometry driven by the state vector
803 estimated from the synthetic data from Sentinel-2 MSI. We choose this cross validation sensor as
804 one different to MSI to stress that one role of a DA system of this sort can be to provide simulated
805 data of sensors other than those used in the DA exercise. Here, we measure the average squared
806 difference between the synthetic HRG data and the DA simulated observations, weighted by the
807 uncertainty in the synthetic data, and term this RMSE in cross-validation. The locations of the
808 synthetic HRG observations are indicated in the lower panel of figure 1 by + symbols.

809

810 FIGURE 2 ABOUT HERE

811

812 Figure 2 shows the error in cross-validation as a function of g for the model first- and second-order
813 difference constraints for the complete case (black circles and squares respectively). There are clear
814 minima for these functions, which provide estimates of the optimal model uncertainty (averaged
815 over all terms). Also shown in the figure is a set of vertical lines that represent the theoretical value
816 of the smoothness term for each of the state vector elements that vary over time (from table 5). For
817 the first order constraint, the minimum of the cross validation function is $g=150$ which is very close
818 to the theoretical values. For the second order constraint the cross validation RMSE minimum at
819 $g=530$ is rather less than the theoretical values. For both cases however, we observe a very broad
820 minimum, so there is quite a large range of values of g that allow almost equally good prediction of

821 the synthetic cross validation HRG observations.

822

823 TABLE 8 ABOUT HERE

824

825 Tables 8 provides statistics on the uncertainty reduction, (the posterior uncertainty estimate from the
826 DA relative to that after solving for each sample separately and assuming the prior uncertainty
827 where there are no observations). The average improvement in uncertainty is 4.07 for the first order
828 constraint and 2.73 for the second order difference constraint. This is very significant but it must be
829 remembered that 4/5 of the samples in the ‘single obs’ solution have only the prior constraint and
830 uncertainty. Examining only locations where observation lie (i.e. ignoring interpolation
831 performance relative to the *a priori* estimate), we see the uncertainty reduction drop by nearly 50%
832 in this case, down to 2.20 for the first order constraint and 1.30 for the second difference constraint.
833 From those figures, we would suppose the first order constraint to be greatly superior to the second
834 order constraint, but if we look at the plots in figure 1, the second order constraint results seem to
835 have more reasonable uncertainty bounds than the other results. This is at least partially because the
836 apparent uncertainty resulting from the DA is strongly dependent on the value of g used in the
837 model constraint: the higher the value of g , the smoother will be the solution and the lower the
838 estimate of uncertainty. The only check we have done on the *veracity* of the solution comes from
839 the cross validation, which is an indirect check: in any non-synthetic experiment we rarely know the
840 ‘truth’ to any great degree of certainty. Since we have a synthetic experiment here, we can however
841 test how frequently the derived solution matches the (synthetic) truth within the claimed uncertainty
842 bounds. One reasonable summary measure of this is the percentage of true values of state vector
843 elements that lie within the 95% credible interval claimed by the DA results. These are shown in
844 table 8. We can see that for the ‘single obs’ estimates (no regularisation), only around 64% of the
845 state vector lies within the 95% credible interval claimed by the solution. The figure is as low as
846 58% for TC_{dm} . We can suppose the average estimated uncertainty then to be only around 67% of

847 the true value, i.e. we should inflate the estimated uncertainty by a factor of around 1.5. This would
848 apply equally to the results in table 6. We see almost the same value for the first order constraint,
849 which suggests the reduction in uncertainty by a factor of 2.2 is likely true. For the second order
850 difference constraint however, around 84% (table 8) of the sample lie within the uncertainty bounds,
851 so here, a better estimate of the uncertainty reduction might be around 1.70 rather than the 1.30
852 reported. This apparent under-reporting of the uncertainty is worthy of comment and there could be
853 several reasons for this. One explanation could be that we are simply under-estimating the
854 uncertainty from the approximations made when calculating the Hessian for the observation
855 operator. A more likely reason is non-linear effects in the treatment of uncertainties. In spite of our
856 attempt to account for gross non-linear impacts through parameter transformations, residual non-
857 linear effects may be causing this under-estimation of uncertainty by a factor of around 1.5.

858

859 FIGURE 3 ABOUT HERE

860 FIGURE 4 ABOUT HERE

861

862 **3.4 DA: Cloudy scenario**

863 Figure 3 shows the DA results for the cloudy scenario. This is a much more realistic test for a DA
864 system. The task now is not only to reduce the uncertainty at the points where we have observations
865 but also to try to provide an effective interpolation over data gaps. The cross validation plots for this
866 case are shown in figure 2 (white circle and square) and provide a much more narrow minimum.
867 This implies that to achieve acceptable results in cross validation, the range of g values that can be
868 tolerated is much more restricted. The minima of these functions however are well within the
869 bounds of the cross validation results for the ‘complete’ scenario and the optimal g indicated very
870 similar to that obtained from the previous results. This indicates that the method for estimating g is
871 quite robust, even when there are large data gaps. Unsurprisingly, the absolute value of the cross
872 validation RMSE is higher for the cloudy case, indicating poorer performance in prediction for this

873 lower quality dataset.

874

875 TABLE 9 ABOUT HERE

876

877 Table 9 shows the reduction in uncertainty for this experiment. One striking feature of these is that
878 the percentage of cases within the credible interval is now above 80% in both cases, meaning that
879 the reported uncertainties are close to the true values. Whilst the apparent reduction in uncertainty is
880 apparently quite small (indeed, there is an increase in uncertainty for some state vector elements) at
881 1.53 for the first order constraint and 1.14 for the second order, when weighed against the improved
882 statistical representation, these rise to values directly comparable with the results from the previous
883 experiment. The credible intervals shown in figure 3 are now realistic representations of the state
884 vector elements and their uncertainties, achieved with only 50% of the samples of the previous
885 experiment and with large data gaps, which is an important result.

886

887 Figure 4 shows the posterior correlation matrices (the inverse Hessian matrix) for the cloudy
888 scenario. The general pattern of this matrix for the ‘complete’ scenario is rather similar so not
889 shown here. Obviously, the correlation is unity along the leading diagonal. Another important
890 feature is that the broad patterns of positive and negative correlations that we noted for the ‘single
891 obs’ solutions remains here. There is negative correlation between s_1 and all terms by TLAI. There
892 is negative correlation between TLAI and TC_{ab} and TC_w but positive correlation with TC_{dm} . These
893 patterns are consistent for both constraints used. We notice then that the application of the dynamic
894 model (regularisation) in time does not remove the correlations arising from the inverse Hessian of
895 the observation cost function, but rather it ‘spreads’ uncertainty correlation out in the time domain.
896 This is particularly visible in the second order constraint matrix in figure 4 where we can clearly see
897 this smoothing being greater where there are data gaps (s_1 is a good example of that). Equally,
898 where a part of the state vector has been strongly influenced by the regularisation (e.g. N for the

899 first order constraint) we see very high correlation at all time steps. Another interesting feature of
900 this figure is the fact that for some state vector elements (e.g. N for the second order constraint) we
901 can clearly see the influence of the periodic boundary condition).

902

903 **4 Discussion**

904 **4.1 The value of an EO-LDAS**

905 This paper outlines a scheme for a weak constraint data assimilation system, developed in the ESA
906 EO-LDAS project, designed for integrating Earth Observation data from a variety of sources over
907 arbitrary time scales, and through that to multiple spatial resolutions. It has the potential, via careful
908 definition of the underlying model to be extended to spatial constraints, although this is not
909 explored here. The scheme is designed to allow interface with process models, should they be
910 available, though only an empirical regularisation model is shown in this paper. The core of the
911 system is a set of constraints on: (i) prior estimates of the state vector; (ii) a linear model of the state
912 vector; (iii) observation operator (RT model) predictions of a set of EO data and a DA scheme
913 around these using an iterative bounded optimisation approach (L-BFGS-B).

914

915 In this paper, we have set up and run a synthetic data experiment with EO data mimicking those that
916 might be provided by the MSI sensors on the forthcoming Sentinel-2 platforms. Experiments in DA
917 are conducted for an idealised ‘full coverage’ scenario (5 day sampling) and for a ‘cloudy’ case
918 (average around 10 day sampling but with large data gaps of up to 60 days). The results are
919 compared to baseline experiments where we attempt to estimate the state variable trajectories over
920 the course of a year for a subset of the total state variables (six elements per observation period).
921 The prior term is used only very weakly here, although bounds are set to the state vector elements.
922 Further, we assume that we have direct access to the surface reflectance (as opposed to top of
923 atmosphere radiance), and that the noise on the observations is uncorrelated and of known
924 magnitude. Broadly however, we can claim that the baseline results should be indicative of those

925 that might be obtained from Sentinel-2 data using ‘traditional’ estimation methods. For what we
926 suppose to be a typical observation noise scenario, the uncertainty can be a quite large proportion of
927 the signal for important terms such as LAI, this for a peak LAI of only around 3.7, although on
928 average the uncertainty in TLAI may only be around 5%. This then, relates to the information
929 content of a single MSI observation for this level of noise, assuming some important terms such as
930 leaf angle distribution are known precisely. These results are not surprising but are simply a
931 manifestation of the difficulty of the inference of biophysical parameters from remote radiometric
932 observations: the problem may often be ill-posed (consider the situation if only two wavebands at
933 red and near infrared were available), but even if it is not strictly so, there may not be sufficient
934 information to very well constrain the information we require. In any case, there can be quite high
935 correlation in uncertainty.

936

937 The ways to improve this situation are: (i) to obtain more observations (although more observations
938 does not always translate to more information: consider again sampling at only red and near
939 infrared wavelengths in trying to constrain e.g. leaf water content); or (ii) to add some other forms
940 of information; (iii) average the data. Much *a priori* information has been used in the past to help
941 constrain these problems, but this has often been approached in a rather *ad hoc* manner. Examples
942 include: assuming some terms known, without considering the impact of uncertainty in these, or
943 imposing degrees of smoothness; assuming that some terms are constant over some arbitrary time
944 period; or *post hoc* low pass filtering to the final results. Given its success in other field of science
945 and engineering, many authors have proposed that DA should be seen as the route to integration of
946 the various forms of information one might wish to use to constrain the estimation. Key to DA is the
947 weighting between the various sources of evidence, and key to this is assigning uncertainty
948 correctly to the sources. This is a feature of the approach that dramatically differentiates it from the
949 way in which VIs are mostly used in EO. As we note in the introduction, if we wish to estimate
950 biophysical parameters (such as LAI) there is generally some form of calibration (against ground

951 observations or RT model runs) but it is extremely rare that those model uncertainties are
952 considered in mapping the product. Other processing steps such as angular normalisation may have
953 taken place, but again, any concepts of uncertainty arising from these are on the whole disregarded.
954 All of these issues *could* be addressed within a DA framework, even if the source of the EO
955 information were to be VIs.

956

957 If a biophysical process model is available to predict the development of the state variables that
958 control the remote sensing signal, this can clearly add information to help constrain the problem. If
959 information from the observations feed back to improve the estimates of the parameters controlling
960 the process model or alternatively improve the state estimates, then a better integration of
961 observations and model is achieved, which will likely better constrain additional terms estimated by
962 the process model. This has been argued by Quaife et al. (2008) and others who have worked on
963 integrating EO data and e.g. Carbon flux process models. However, models such as these simply do
964 not provide information on a large number of the variables that affect EO signals, and this is likely
965 to remain the case for the foreseeable future. Exercises in EO-model integration then
966 understandably tend to focus on the points of common linkage (which often is no more than LAI,
967 being supposed linearly related to leaf Carbon) and then applying the ‘traditional’ methods to the
968 remaining parameters (assuming them known or at best constant over time). In this paper, and in the
969 EO-LDAS work in general, we have taken the focus away from working with some specific process
970 model, and tried to consider the more general case and the sorts of constraints that might be
971 appropriate. If no physical model is available, empirical concepts of smoothness in the state
972 variables come to the fore. These ideas become even more important if one considers constraint in
973 the spatial domain, where physical or even biological process models are almost completely lacking
974 to aid biophysical parameter estimation.

975

976 The EO-LDAS scheme that we have built is capable of using any linearised process model and of

977 more general interface to process model codes provided the cost function and its derivatives can be
978 calculated. In the prototype and in this paper we have examined first- and second-order derivative
979 constraints as general, appropriate (empirical) models for biophysical parameter estimation in DA.
980 We have simulated typical profiles of LAI and leaf chlorophyll concentration and rather complex
981 profiles of leaf water concentration and soil brightness and shown that with Sentinel-2 MSI data
982 every 5 days, a reduction in uncertainty by a factor of around 2 might generally be achieved. More
983 interestingly perhaps, after compensation for errors in uncertainty prediction, we saw that similar
984 reductions might be achieved even when there are large data gaps and 50% of the samples lost due
985 to cloud cover.

986

987 We have also demonstrated (figure 2) that it is feasible to estimate the required hyper-parameters
988 from some form of cross-validation exercise to impose an appropriate degree of model uncertainty,
989 and that quite consistent results can be obtained even under cloudy conditions. This is an important
990 practical point for the eventual operationalisation of these methods, but the area requires a little
991 more discussion of practical issues in its implementation.

992

993 Approximate linearization of the RT model variables here, following Weiss et al. (2000), has
994 allowed Gaussian distributions to be assumed throughout. Although we have not directly
995 investigated any residual non-linear effects in this study, some evidence is provided that on average
996 we may be predicting only around 2/3 of the true uncertainty.

997

998 **4.1 Future directions**

999 In this paper, we have only demonstrated DA for a homogeneous observation system, i.e. one for
1000 which we have assumed the spectral sampling (and in effect, spatial resolution) for all observations
1001 is the same. Using the EO-LDAS prototype for spectrally heterogeneous systems is straightforward,
1002 but further work is needed to test the multi-scale concepts that would more generally be required.

1003 Within the existing prototype, the state vector can represent any mixture of temporal or spatial
1004 samples. The concepts of temporal smoothness used here apply equally to the spatial domain
1005 (indeed, such ideas form the basis of the field of geostatistics (e.g. Atkinson and Lewis, 2000)), so
1006 the prototype can be used directly to link a state vector representation on a spatial grid, via
1007 appropriate specification of the matrix A . Indeed, one could consider the experiments performed in
1008 this paper simply as being on a spatial transect, rather than as we have assumed a temporal sampling
1009 pattern. The only practical difference is that in that case, the viewing and illumination angles would
1010 be near identical for all samples.

1011

1012 The EO-LDAS prototype is designed to allow a (relatively) large number of state variables to be
1013 estimated simultaneously in a variational system (> 2000 demonstrated here). One potential
1014 advantage of this is that information can be passed between any of the state vector elements. In
1015 practice, we have only used rather local information transfer in the model constraints applied here
1016 (differences with neighbours in time) and this approach could also be implemented as a sequential
1017 smoother. In viewing the temporal experiment we have performed as effectively equivalent to a
1018 spatial experiment, the neighbourhood need not be very different (i.e., in the spatial sense, we could
1019 follow the approach here and directly connect information in one grid cell to its 8 neighbours).
1020 However, this variational system maintains the capacity for more distant (time or space)
1021 connections, for example in applying multiple scale constraint.

1022

1023 A point that we have not dwelt on in this paper is the time required for processing. This is currently
1024 around several hours for solving for > 2000 state vector elements using 73 samples for what equates
1025 to a single pixel (albeit for all samples over a year). The experiments in this paper were conducted
1026 over around 120 UNIX cores, so quite large-scale experiments are feasible using University
1027 computing resources. Clearly the processing requirements would need to be greatly reduced if such
1028 a system were to be proposed for operational processing. The computer code is not on the whole

written to be fast, but rather to be adequate to learn about using this form of DA. There are various ways in which this might be tackled: clearly the very tight convergence criteria could be somewhat relaxed, and more efficient codes could be written, but there will always be a relatively large overhead on multiple calculations of a radiative transfer model. Pragmatic ways to overcome this issue have mainly in the past dealt with using LUTs or ANNs to sample or approximate the observation operator, but clearly in the DA framework we must consider representational error in any such emulation. One avenue that holds much promise is that of Gaussian Process (GP) emulators (Kennedy and O'Hagan, 2000, 2001), a form of regression that has been successfully used to simulate computationally costly models runs through simple functional approximations. The great benefit of this latter approach is that uncertainties in the emulated model are included and that derivatives of the model can also be easily produced. If we consider the observation operator as a sampled function with GP emulation, it is interesting to note that the underlying concepts implying smooth interpolation with treatment of representation uncertainty are of course the same as we are performing in the temporal (or indeed spatial) process model in the DA.

1043

1044 **5 Conclusions**

The EO-LDAS prototype that is described in this paper has been demonstrated to be capable of simultaneously estimating a state vector of over 2000 elements of surface biophysical characteristics in a synthetic experiment using simulated Sentinel-2 MSI data. Although the processing time required for this is currently a little long, this is a significant step in the size of such problems that can be tackled simultaneously. The ability to do this derives from the use of AD-generated adjoint code for the observation operator at the heart of the DA system.

1051

The DA scheme that has been developed is a weak constraint variational system. The value of such a scheme has been demonstrated using the synthetic MSI data to show a reduction in uncertainty of up to around 2 when a linear dynamic model is used in the DA. The linear dynamic model is

1055 proposed as a general implementation that can potentially be interfaced to biophysical process
1056 models through linearization. It is used in this paper with first and second-order derivative
1057 constraints (zero- and first-order process models) which are shown to be sufficient to track rather
1058 complex biophysical parameter trajectories via a radiative transfer model ‘observation operator’
1059 interface to the synthetic EO data.

1060

1061 We have noted at various points in this text, that some aspects of the EO-LDAS prototype are still
1062 under development of testing, but what actually is provided by the prototype code is a functioning
1063 tool for exploring many issues in DA and for estimating information on surface biophysical
1064 parameters. The tool is designed as a weak constraint variational system, but we have argued that it
1065 can also be used sequentially as it stands. We have demonstrated the use of the tool and of DA
1066 concepts in reducing uncertainty in biophysical parameter estimation in a temporal sense, but also
1067 argued the equivalence of this (in DA in general, but in the tool specifically) for the spatial domain
1068 as well. We have used only empirical ‘regularisation’ concepts in demonstrating the DA, but noted
1069 that these are powerful general concepts that are extremely useful, particularly if biophysical
1070 models do not treat some of the parameters we are concerned with. In the more general case though,
1071 any linearization of a more process-driven model can be directly interfaced to the EO-LDAS
1072 prototype.

1073

1074 There is clearly quite a long way to go from initial experiments with relatively slow computer codes
1075 to an operational system for land data information extraction from EO, i.e. an operational EO-
1076 LDAS, but the concepts explored here demonstrate the power and potential flexibility of such an
1077 approach.

1078

1079 **Acknowledgements**

1080 We gratefully acknowledge the support of ESA through the EO-LDAS project 22205/09/I-EC for

1081 funding this work. We also acknowledge the support of the (UK) National Environment Research
1082 Council (NERC) National Centre for Earth Observation (NCEO) for its support of several of the
1083 personnel involved in this work. We would further like to thank the attendees of the EO-LDAS
1084 Community Workshop held in ESA ESRIN in November 2009 for their feedback and inputs to this
1085 study.

1291 **Table Captions**

1292 Table 1. Spatial resolution, Central wavelength and bandwidths for Sentinel-2 MSI (ESA, 2010).

1293 Table 2. Summary of observation operator state variables.

1294 Table 3. Transformations applied to approximate linearise state variable response.

1295 Table 4. Upper and lower bounds for the state vector terms (in transformed space, where
1296 appropriate) used in the simulations, along with the temporal trajectory assumed.

1297 Table 5. Model uncertainty γ for each parameter, calculated from the synthetic model state vector.
1298 TC_{dm} and N were kept constant, so have no theoretical model uncertainty associated.

1299 Table 6: Mean posterior uncertainty. Figures refer to the complete daily time series, while figures in
1300 brackets refer to the mean posterior uncertainty only considering the dates where observations are
1301 available.

1302 Table 7: Single observation posterior correlation matrix. Elements above the main diagonal show
1303 the results for DoY 186, whereas the elements below the main diagonal represent the median of all
1304 dates.

1305 Table 8: Uncertainty reduction relative to the single observation inversion, as well as percentage of
1306 cases where the true parameter lies within the estimated 95% credible interval. Results for non-
1307 cloudy scenario are reported. both complete time series.

1308 Table 9: Uncertainty reduction relative to the single observation, as well as percentage of cases
1309 where the true parameter lies within the estimated 95% confidence interval. Results for cloudy
1310 scenario.

1318 **Figure Captions**

1319 Figure 1. Base level state vector estimated from inverting single observations, (left column) and for
1320 model uncertainty unknown and estimated through cross-validation – first difference constraint
1321 (central column) and second difference constraint (third column). Results for each of the six
1322 parameters are shown in rows. True values are shown as a dashed line. The full lines are the
1323 posterior means, and the shaded area represents the associated ± 1.96 standard deviations interval.
1324 MSI observations are shown as open symbols. Crosses along the bottom of the third row indicate
1325 the location of the cross validation acquisition dates.

1326 Figure 2. Error in cross validation scaled by observational uncertainty for varying model uncertainty
1327 γ for first and second order constraints. Vertical lines around 200 represent the theoretical value of γ
1328 for each of the 4 time-varying state variables using a first order constraint, and vertical lines around
1329 5000 represent the theoretical values for γ for each of the 4 time-varying state variables using
1330 second order constraint.

1331 Figure 3. Base level state vector estimated from inverting single observations, (left column) and for
1332 model uncertainty unknown and estimated through cross-validation – first difference constraint
1333 (central column) and second difference constraint (third column). Reduced number of acquisitions
1334 due to cloud cover scenario. Results for each of the six parameters are shown in rows. True values
1335 are shown as a dashed line. The full lines are the posterior means, and the shaded area represents the
1336 associated ± 1.96 standard deviations interval. MSI observations are shown as open symbols.
1337 Crosses along the bottom of the third row indicate the location of the cross validation acquisition
1338 dates.

1339 Figure 4. Posterior correlation matrices for the cloudy scenario. Labels indicate the location of the
1340 first day for component of the state vector.

Figures

Figure 1. Base level state vector estimated from inverting single observations, (left column) and for model uncertainty unknown and estimated through cross-validation – first difference constraint (central column) and second difference constraint (third column). Results for each of the six parameters are shown in rows. True values are shown as a dashed line. The full lines are the posterior means, and the shaded area represents the associated ± 1.96 standard deviations interval. MSI observations are shown as open symbols. Crosses along the bottom of the third row indicate the location of the cross validation acquisition dates.

 1391 **4 time-varying state variables using second order constraint.**

Figure 3. Base level state vector estimated from inverting single observations, (left column) and for model uncertainty unknown and estimated through cross-validation – first difference constraint (central column) and second difference constraint (third column). Reduced number of acquisitions due to cloud cover scenario. Results for each of the six parameters are shown in rows. True values are shown as a dashed line. The full lines are the posterior means, and the shaded area represents the associated ± 1.96 standard deviations interval. MSI observations are shown as open symbols. Crosses along the bottom of the third row indicate the location of the cross validation acquisition dates.

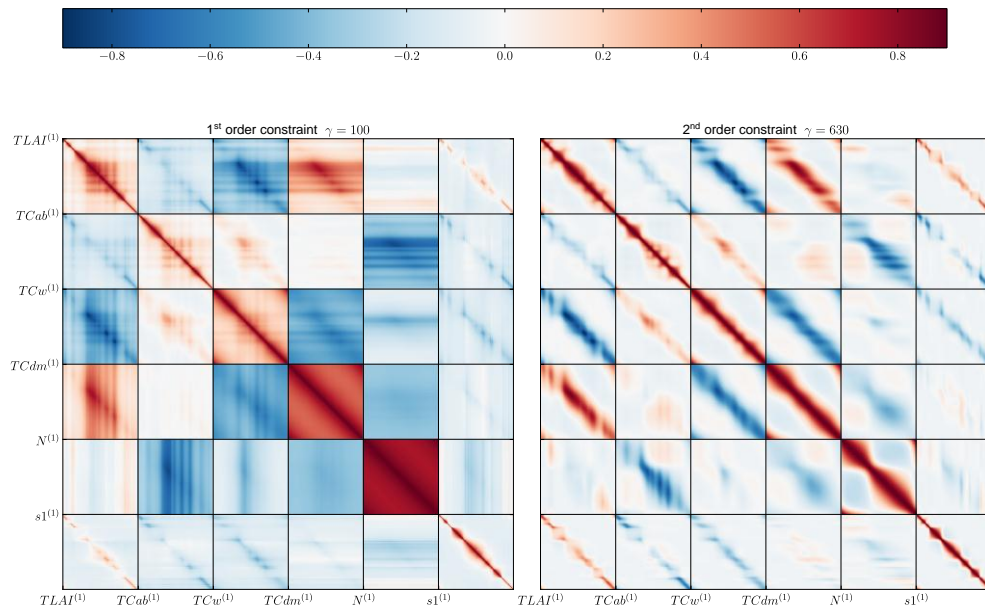

Figure 4. Posterior correlation matrices for the cloudy scenario. Labels indicate the location of the first day for component of the state vector.
